Session 2: Machine Learning setup

# Supervised Machine Learning

Learning and information

The bias-variance trade-off

Empirical Risk Minimization

# Supervised Machine Learning

Learning and information

# Learning like the twenty-question game

- Assume Nature has picked one function among  $K$  and we want to reveal this function
- Assume we have an oracle answering YES or NO when we ask a question about this function
- What is the optimal number  $n$  of questions to ask to find the unknown function?

## Brute force learning

### Finite case

- ISSUE: How many questions with answers YES or NO one has to ask the oracle to find THE function among  $K$  functions?
- STRATEGY: Proceed recursively by splitting the set of functions in two groups and asking whether THE function is the first group and removing the group which does not contain the function. This leads to the identification of the desired function with about  $\log K$  questions.
- ANSWER: Number of questions  $n = \frac{\log K}{\log 2}$
- NB: this quantity represents the number of bits of information characterizing the function in the set of  $K$  functions

# Shannon's Information theory

## The origin of the $\log K$

- Related to the entropy of a distribution  $P$  in information

theory: 
$$H(P) = - \sum_{k=1}^K P(k) \log P(k)$$

- The entropy is the number of bits to encode a collection of  $K$  symbols (functions)

# From questions to data

## Zero error case

- Notations: Domain space  $\mathcal{X}$  and label space  $\mathcal{Y} = \{0, 1\}$
- ISSUE: How many examples  $(x_i, y_i) \in \mathcal{X} \times \mathcal{Y}$  are required to find among a *finite* collection (size  $K$ ) of indicator functions  $f : \mathcal{X} \rightarrow \{0, 1\}$  the desired one?
- SAME ANSWER: Number of examples  $n = \frac{\log K}{\log 2}$
- STRATEGY: One has to find a vector  $x_i$  such that half of the functions take value 1 and the other half take value 0 and ask the oracle whether the desired function takes value 1 or 0 on this vector and discard those functions taking the opposite value. Apply this  $n$  times.

# Probably approximately correct learning

## Zero error case

- REMARK: it may be hard to find such an  $x_i$  which splits the collection of functions in two.
- NEW MODEL: Assume  $X_1, \dots, X_n$  is an IID sample
- QUESTION: How many examples  $(X_i, Y_i)$  are required to find among a finite collection of indicator functions  $f : \mathcal{X} \rightarrow \{0, 1\}$  the one that with probability  $1 - \delta$  is  $\varepsilon$ -close to the desired one?
- ANSWER: Number of examples

$$n = \frac{\log K - \log \delta}{\varepsilon}$$

(Proof left as an exercise)

# Probably approximately correct learning

## General case

- ASSUME: among  $K$  functions, NONE of them commits zero error on the sample  $(X_i, Y_i)$ .
- SAME ISSUE AS BEFORE
- ANSWER: Number of examples on average

$$n = \frac{\log K - \log \delta}{\epsilon^2}$$

Same dependency on  $K$ , the only change is in the constant.

(Proof coming next)

## Questions raised

- Proof arguments for PAC learnability (finite case)
- PAC: From finite to infinite collection of functions
- From "strategies" to "learning algorithms"
- What is lost through sampling?

# Supervised Machine Learning

The bias-variance decomposition in Machine Learning

## General setup

### Notations

- Goal of learning: an optimal decision function  $h^* : \mathcal{X} \rightarrow \mathcal{Y}$   
 $\mathcal{X}$ : domain set,  $\mathcal{Y}$ : label set
- Input of learning:
  - **Training data:** a set of labeled data

$$D_n = \{(X_1, Y_1), \dots, (X_n, Y_n)\}$$

of size  $n$ , where the  $(X, Y)$ 's are in  $\mathcal{X} \times \mathcal{Y}$

- **Hypothesis space:** a collection  $\mathcal{H}$  of candidate decision functions  $h : \mathcal{X} \rightarrow \mathcal{Y}$
- Output of learning: an empirical decision function  $\hat{h}$  in the hypothesis space  $\mathcal{H}$  estimated from training data  $D_n$
- Reference in  $\mathcal{H}$ : the best decision function  $\bar{h}$  in the class (the more data, the closer  $\hat{h}$  to  $\bar{h}$ )

# The key trade-off in Machine Learning

- Denote by  $L(h)$  the error measure for any decision function  $h$
- We have:  $L(\bar{h}) = \inf_{\mathcal{H}} L$  , and  $L(h^*) = \inf L$
- Bias-Variance type decomposition of error for any output  $\hat{h}$  :

$$L(\hat{h}) - L(h^*) = \underbrace{L(\hat{h}) - L(\bar{h})}_{\text{estimation (stochastic)}} + \underbrace{L(\bar{h}) - L(h^*)}_{\text{approximation (deterministic)}}$$

Hypothesis class  $\mathcal{H}$

## About approximation error

- Cybenko (1989) - Denseness result in the spirit of Stone-Weierstrass showing that any linear combination of compositions of sigmoid with linear functions is dense wrt the supremum norm in the space of continuous functions over the  $d$ -dimensional unit cube.
- Barron (1994) - Approximation error bound involves a parameter quantifying the smoothness of the target function.
- Status of this question in the regression setup:
  - For kernel machines: a full theory is available thanks to Smale (2003), Steinwart (2008).
  - For deep learning: recent work by Grohs, Perekrestenko, Elbrächter, and Bölcskei (2019) .
  - In the classification setup, tough problem, still open issue...

# What all student know

The bias-variance trade-off in regression

# The regression model

- Goal of learning:  $h^* : \mathbb{R}^d \rightarrow \mathbb{R}$
- Observations: IID random pairs  $(X_i, Y_i) \in \mathbb{R}^d \times \mathbb{R}$  :

$$Y_i = h^*(X_i) + \varepsilon_i, \quad i = 1, \dots, n$$

where  $\varepsilon_i$  is a random noise variable independent of  $X$

- We shall use a vector notation as follows:

$$\mathbf{Y} = \mathbf{h}^* + \varepsilon$$

where the three terms are all in  $\mathbb{R}^n$

## Vector notations

- Elements in  $\mathbb{R}^n$ :

$$\mathbf{Y} = (Y_1, \dots, Y_n)^T,$$

$$\varepsilon = (\varepsilon_1, \dots, \varepsilon_n)^T$$

- Image vectors: for any  $h \in \mathcal{H}$ , we use the bold characters as

$$\mathbf{h} = (h(X_1), \dots, h(X_n))^T$$

- The image of data points through elements of  $\mathcal{H}$  by

$$\mathcal{H}(X) = \{\mathbf{h} = (h(X_1), \dots, h(X_n))^T, : h \in \mathcal{H}\}$$

- Norm in  $\mathbb{R}^n$  :

$$\forall u = (u_1, \dots, u_n)^T \in \mathbb{R}^n, \quad \|u\|^2 = \sum_{i=1}^n u_i^2$$

## Least square estimator (LSE)

- Definition of the LSE :

$$\hat{\mathbf{h}}_n = \arg \min_{\mathbf{h} \in \mathcal{H}(X)} \frac{1}{n} \|\mathbf{Y} - \mathbf{h}\|^2$$

where  $\mathcal{H}(X) = \{\mathbf{h} = (h(X_1), \dots, h(X_n))^T, : h \in \mathcal{H}\}$

- Error measure of the LSE:

$$L(\hat{h}_n) = \frac{1}{n} \mathbb{E}(\|\mathbf{h}^* - \hat{\mathbf{h}}_n\|^2)$$

# Gaussian linear model in $\mathbb{R}^d$

## Two additional assumptions

- The hypothesis space  $\mathcal{H}$  is the class of *linear* functions of rank  $d$
- The noise vector  $\varepsilon = (\varepsilon_1, \dots, \varepsilon_n)^T$  is a *gaussian* random vector in  $\mathbb{R}^n$  with distribution  $\mathcal{N}_n(0, \sigma^2 I_n)$

# Linear models in $\mathbb{R}^d$

## Examples

Notations:  $x = (x^{(1)}, \dots, x^{(d)})^T \in \mathbb{R}^d$

- Linear regression:  $h(x) = \sum_{k=1}^d \beta_k x^{(k)}$
- Basis/frame expansion (Fourier, splines, wavelets, etc.)
- Additive models:  $h(x) = \sum_{k=1}^d f_k(x^{(k)})$
- Piecewise constant regression (taking into account breakpoints)

## LSE in linear regression

- Denote by  $\mathbf{X}$  the data matrix ( $n \times d$ )
- Least square estimate:  $\hat{\mathbf{h}}_n = \mathbf{X}(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y} = \hat{\Pi} \mathbf{Y}$

## Bias-variance decomposition (1/2)

### Derivation

- First note that:  $\hat{\mathbf{h}}_n = \hat{\Pi}\mathbf{Y} = \hat{\Pi}(\mathbf{h}^* + \varepsilon)$  and then

$$\mathbf{h}^* - \hat{\mathbf{h}}_n = (I_n - \hat{\Pi})\mathbf{h}^* - \hat{\Pi}\varepsilon$$

- Note that  $\hat{\Pi} : \mathbb{R}^n \rightarrow \mathbb{R}^n$  the orthogonal projection onto  $\mathcal{H}(X)$ :

$$\hat{\Pi} \circ \hat{\Pi} = \hat{\Pi}$$

- By orthogonality of the images of  $I_n - \hat{\Pi}$  and  $\hat{\Pi}$ :

$$\begin{aligned} L(\hat{h}_n) &= \frac{1}{n} \mathbb{E}(\|\mathbf{h}^* - \hat{\mathbf{h}}_n\|^2) \\ &= \frac{1}{n} \mathbb{E}(\|(I_n - \hat{\Pi})\mathbf{h}^*\|^2 + \|\hat{\Pi}\varepsilon\|^2) \end{aligned}$$

## Bias-variance decomposition (2/2)

### Result

- Using an additional technical result (next slide):

$$\begin{aligned} L(\hat{h}_n) &= \frac{1}{n} \mathbb{E}(\|\mathbf{h}^* - \hat{\mathbf{h}}_n\|^2) \\ &= \frac{1}{n} \mathbb{E}(\|(I_n - \hat{\Pi})\mathbf{h}^*\|^2 + \|\hat{\Pi}\varepsilon\|^2) \\ &= \underbrace{\frac{1}{n} \mathbb{E}(\|(I_n - \hat{\Pi})\mathbf{h}^*\|^2)}_{\text{bias}} + \underbrace{\sigma^2 \frac{d}{n}}_{\text{variance}} \end{aligned}$$

- Used in model selection (e.g. AIC)  $\rightarrow$  discussed in next class

## Explanation of the $d/n$ term

Property on the norm of projections of gaussian random vectors:

- Assume  $\mathbf{Z}$  is a gaussian random vector  $\mathcal{N}_n(0, I_n)$  in  $\mathbb{R}^n$ ,  $\mathcal{H}$  is a linear subspace of  $\mathbb{R}^n$  and  $\Pi : \mathbb{R}^n \rightarrow \mathbb{R}^n$  a linear projection onto  $\mathcal{H}$
- Then: the random vector  $\Pi_{\mathcal{H}}\mathbf{Z}$  has gaussian distribution  $\mathcal{N}_n(0, \Pi)$  on  $\mathbb{R}^n$  (linear transformation of a gaussian is a gaussian)
- Furthermore:  $\|\Pi\mathbf{Z}\|^2$  follows a chi-square distribution with

$$\mathbb{E}(\|\Pi\mathbf{Z}\|^2) = \dim(\mathcal{H})$$

# How Machine Learning takes over linear regression

- ① What if non-additive noise? Other tasks than regression?
- ② From linear to nonlinear models
- ③ What replaces the dimension  $d$  as a measure of complexity in nonlinear models?
- ④ Is the  $d/n$  rate also typical for larger hypothesis classes?  
What if  $d$  larger than  $n$  ?

# Supervised Machine Learning

## Empirical Risk Minimization (ERM)

# The ERM principle

## Definition

- Loss function:  $\ell : \mathcal{Y} \times \mathcal{Y} \rightarrow [0, +\infty]$
- Empirical risk of a decision rule  $h$ : this is a data-dependent functional

$$\hat{L}_n(h) = \frac{1}{n} \sum_{i=1}^n \ell(h(X_i), Y_i)$$

- ERM = Empirical Risk Minimization

Learning from training data amounts to solving the following optimization problem

$$\hat{h}_n = \arg \min_{h \in \mathcal{H}} \hat{L}_n(h)$$

where the minimization is restricted to the hypothesis space.

# The ERM principle

## Main questions

- ① The question of consistency: convergence of  $\hat{h}_n$  wrt the sample size  $n$ ?
- ② What is the cost incurred for using training data instead of the actual data?
- ③ What is the nature of the trade-off to calibrate the complexity of the hypothesis space  $\mathcal{H}$ ?

# Overfitting vs. underfitting

Less is more:

- It turns out that considering all measurable functions leads to overfitting  $\Rightarrow \mathcal{H}$  has to be a restricted class!

But greed is good:

- Algorithms which have the capacity to overfit means they have high representation power (arbitrary small approximation error)

## The notion of *true* error

- Assumption:  
 $(X, Y)$  is a pair of random variables with joint distribution  $P$
- True error of a decision rule  $h$ : this is a distribution-dependent functional

$$L(h) = \mathbb{E}(\ell(h(X), Y)) = \int \ell(h(x), y) dP(x, y)$$

# Optimal elements, consistency and bounds

- Bayes rule  $h^*$  and Bayes error  $L^*$

$$h^* = \arg \min_h L(h) \quad \text{and} \quad L^* = L(h^*)$$

- (Strong) Consistency of an inference principle  $\hat{h}_n$

$$L(\hat{h}_n) \rightarrow L^* , \quad \text{almost surely}$$

- The nonasymptotic bounds Eldorado:

$$L(\hat{h}_n) - L^* \leq U(n, \mathcal{H}) \quad \text{whp}$$

# Estimation vs. approximation error

## Extension of bias-variance decomposition

- Proof idea: Add and retrieve  $\widehat{L}(\widehat{h}_n)$ ,  $\widehat{L}(\bar{h})$ ,  $L(\bar{h})$ , then use the definition of ERM to upper bound the sum. Difference between  $L$  and  $\widehat{L}$  appear twice.
- We have:

$$L(\widehat{h}_n) - L^* \leq \underbrace{2 \sup_{h \in \mathcal{H}} |L(h) - \widehat{L}_n(h)|}_{\text{estimation (stochastic)}} + \underbrace{L(\bar{h}) - L^*}_{\text{approximation (deterministic)}}$$

# Finite hypothesis class

## Generalization error bound for ERM

- Assume that the hypothesis class  $\mathcal{H}$  of decision functions is finite and  $h^* \notin \mathcal{H}$
- Then, we have, for any  $\delta$ , with probability at least  $1 - \delta$ :

$$\forall h \in \mathcal{H}, \quad L(h) \leq \hat{L}_n(h) + \sqrt{\frac{\log |\mathcal{H}| + \log\left(\frac{1}{\delta}\right)}{2n}}$$

- $\log |\mathcal{H}| = \log K \rightarrow$  Statement in the introduction, see!

# Finite hypothesis class

## Sketch of proof

- Hoeffding's inequality:

- Consider  $Z_1, \dots, Z_n$  IID over  $[0, 1]$  and  $\bar{Z}_n = \frac{1}{n} \sum_{i=1}^n Z_i$

- We have, for any  $t > 0$

$$\mathbb{P}\{\bar{Z}_n - \mathbb{E}(Z_1) > \varepsilon\} \leq \exp(-2n\varepsilon^2)$$

- Union bound: For any two measurable sets  $A, B$ , we have:

$$\mathbb{P}\{A \cup B\} \leq \mathbb{P}\{A\} + \mathbb{P}\{B\}$$
